We demonstrate integration of individual light-emitting carbon nanotubes with silicon microdisk resonators. Photons emitted from nanotubes are efficiently coupled to whispering gallery modes, circulating within the disks and lighting up their perimeters. Furthermore, we control such emission by tuning the excitation wavelength in and out of resonance with higher order modes in the same disk. Our results open up the possibilities of using nanotube emitters embedded in photonic circuits that are individually addressable through spectral double resonance. © 2013 AIP Publishing LLC [http://dx.doi.org/10.1063/1.4802930]

Advances in silicon photonics have enabled on-chip integration of various devices, expanding the capabilities of monolithic photonic circuits. For further scaling and increased functionality, however, integration of nanoscale emitters is desirable. Unfortunately, partly due to the fact that silicon is an indirect gap semiconductor, coupling of individually addressable nanoscale emitters to silicon photonics devices has remained a challenge.

In this regard, carbon nanotubes (CNTs) are promising because they are room-temperature telecom-band emitters that can be directly synthesized on silicon and be electrically driven. In particular, as-grown air-suspended CNTs show excellent optical properties, making them ideal for use as individual emitters compared to on-substrate or solution based materials.

As a silicon photonics device for coupling with air-suspended CNTs, microdisk resonators have many desirable properties. They are a commonly used microcavity structure, supporting whispering gallery modes (WGMs) where optical waves are guided along the circumference of the disk by continuous internal reflection. Because they can have ultra-high quality factors and small mode volumes, WGMs are suited for coupling with nanoscale emitters such as quantum dots. It is relatively easy to tune the cavity resonance to the emitter wavelength by fabricating disks with an appropriate diameter, and the three-dimensional structure of post-supported microdisks is compatible with air-suspended CNTs. Furthermore, they can be coupled to waveguides with high efficiency because they are traveling-wave resonators, making them a preferred choice compared to planar cavities for integration in silicon photonics.

Here, we report on the integration of individual CNT emitters with silicon microdisks using fabrication processes compatible with standard silicon photonics. When photons emitted from nanotubes are coupled to the WGMs of the microdisks, emission enhancement occurs in a narrow spectral windows corresponding to the modes. Spatial imaging of the emission at the WGM wavelength shows the peripheral of the disk illuminated by the coupled CNT emission that circulates within the microdisk. In addition, we show that the excitation laser can also be coupled to whispering gallery modes in the same disk, allowing for non-local control over nanotube emission.

We fabricate microdisks from a silicon-on-insulator wafer with a 260-nm-thick top Si layer and a 2000-nm-thick buried oxide layer. Electron beam lithography and dry-etching processes are used to form doughnut-shaped trenches in the top Si layer. In order to create a post-supported disk structure, the buried oxide layer is etched in buffered hydrofluoric acid. A scanning electron microscope image of a typical microdisk prior to nanotube growth is shown in Fig. 1(a).

The devices are characterized with a home-built laser-scanning confocal photoluminescence (PL) microscopy system. An output of a wavelength-tunable continuous-wave Ti:sapphire laser is focused onto the sample by an objective lens to a spot size of ~1 μm. PL is coupled to a 300-mm spectrometer through a pinhole in a confocal configuration. An InGaAs photodiode array is used for detection and PL images are collected with a steering mirror. All measurements are done in air at room temperature.

A PL spectrum of a microdisk taken with an excitation wavelength λ_ex = 755 nm and a power P = 1 mW is shown as a red curve in Fig. 1(b). A forest of resonances consisting of WGMs as well as Fabry-Perot modes is visible within the silicon bandgap emission.

An interesting observation is that the emission intensity decreases by a factor of ~5 when λ_ex is tuned to 748 nm [green curve in Fig. 1(b)]. To investigate this strong excitation wavelength dependence, PL excitation (PLE) spectroscopy is performed [Figs. 1(c) and 1(d)]. We interpret the cross hatch pattern in the PLE map [Fig. 1(d)] as coupling of cavity modes at both excitation and emission wavelengths. The vertical streak-like features correspond to microdisk modes coupled to silicon emission, and the horizontal streaks represent modes coupled to the excitation laser. The intersections of vertical and horizontal streaks indicate simultaneous resonance of the excitation and emission, which allows control over PL intensity by about an order of magnitude [Fig. 1(b)].

The PLE spectrum [Fig. 1(c)] shows clear resonances with quality factors of ~100, but precise mode assignment is difficult at these wavelengths because of high mode orders and strong absorption. Nevertheless, examination of
reflectivity and PL images shows that PL is enhanced at the edges of the disk when the polarization matches the radial direction [Figs. 1(e)–1(g)]. Such a polarization dependence is consistent with what one expects for WGMs with transverse-electric (TE) polarization. The coupling of excitation laser to WGMs implies that the laser photons can propagate within the disk at resonance, allowing for non-local excitation.

In order to couple single CNTs to microdisk WGMs, it is necessary to choose a disk with an appropriate diameter such that a suitable WGM exists at the emission wavelength of nanotubes. In addition, as CNTs interact primarily with light polarized along their axis,\textsuperscript{22,24,25} it is also important to consider the mode polarization. WGMs can have either TE or transverse-magnetic (TM) polarization, and we expect TE modes to have better coupling with the nanotubes since CNTs suspended onto the microdisks will be parallel to the substrate.

We identify WGMs at CNT emission wavelengths by spin coating nanotube solution on the microdisks and performing PL measurements in a manner similar to experiments done on photonic crystal microcavities.\textsuperscript{14} Figure 2(a) shows spectra from a few microdisks with different diameters, in which the sharp WGMs show up as a result of broad emission from nanotubes. The mode wavelengths shift with diameter as expected.

The disk diameter dependence of WGMs is summarized in Fig. 2(b). We assign the TE modes by comparing the data to an analytical model with no adjustable parameters.\textsuperscript{17} The TM modes are identified by a weaker dependence on the diameter, which is a result of their smaller effective index of refraction. Within the wavelength range of interest for coupling with CNTs (1300–1500 nm), we confirm the presence of a few TE modes.

We now investigate CNT emitters integrated with silicon microdisks [Fig. 3(a)]. Another electron beam lithography step is performed to define catalyst windows at outer edges of the doughnut-shaped trenches. Single-walled CNTs are grown by chemical vapor deposition using ethanol as a carbon source.\textsuperscript{26} Catalyst solution is prepared by ultrasonically boiling 5.0 mg of cobalt(II) acetate tetrahydrate and 50.0 mg
of fumed silica in 40.0 g of ethanol. We spin coat and lift off the catalyst solution, and the samples are annealed in air for 5 min at 400 °C prior to growth. The samples are then placed in a quartz tube furnace, and the temperature is elevated to 800 °C while flowing Ar with 3% H2. Ethanol is introduced into the WGM circulate within the microdisk, and this can be visualized through spectrally resolved PL imaging as in the case of WGM at Si emission wavelengths [Fig. 4(a)]. Using a higher resolution grating, we collect PL spectra as we raster the laser spot over the scan area, and fit them with two Lorentzian functions corresponding to the WGM peak and the direct CNT emission peak [Fig. 4(b)]. We find that the measured quality factor of the WGM is limited by spectrometer resolution to be ~3000, which is already two orders of magnitude larger compared to the case of Si PL, the emission is enhanced by a factor of ~10 at double resonance compared to off-resonant conditions [Fig. 3(e)], allowing non-local control over nanotube emission through spectral tuning.

Different from the direct measurement of the suspended CNT, the PLE map for coupled emission shows strong modulation of intensity with changes in the excitation wavelength. As mentioned previously, there exist WGMs at these wavelengths as well, and they can cause enhancements of the excitation efficiency when excitation is resonant with a WGM. When both the excitation and emission are in resonance with WGMs, we meet the doubly resonant condition of the cavity. Similar to the case of Si PL, the emission is enhanced by a factor of ~10 at double resonance compared to off-resonant conditions [Fig. 3(e)], allowing non-local control over nanotube emission through spectral tuning.

The photons that couple to the WGM circulate within the microdisk, and this can be visualized through spectrally resolved PL imaging as in the case of WGM at Si emission wavelengths [Fig. 4(a)]. Using a higher resolution grating, we collect PL spectra as we raster the laser spot over the scan area, and fit them with two Lorentzian functions corresponding to the WGM peak and the direct CNT emission peak [Fig. 4(b)]. We find that the measured quality factor of the WGM is limited by spectrometer resolution to be ~3000, which is already two orders of magnitude larger compared to a simple planar cavity.11

In Figs. 4(c) and 4(d), spectrally resolved PL images corresponding to the WGM and direct CNT emission are presented. It is clear that nanotube emission coupled to the WGM circulates within the disk and illuminates the circumference [Fig. 4(c)], showing that CNT emission is efficiently guided into the silicon photonic structure. We note that the coupling occurs through the evanescent fields of the WGM, as the nanotube is located outside of the resonator. This is in contrast to the case of quantum dots that are embedded within the microdisks, and our results show that the evanescent fields are strong enough to couple the nanotube emission into the WGM.

The direct emission from the CNT is centered on the nanotube itself as expected [Fig. 4(d)], although one can observe a lower intensity spot at the opposite side of the disk. We interpret the existence of such a remote spot in terms of in-plane Fabry-Perot mode within the microdisk.21 Such an interpretation is also consistent with the image of the WGM [Fig. 4(c)], which shows larger intensity near that spot.
Our results demonstrate the feasibility of integrating telecom-wavelength nanotube emitters in silicon photonics, opening up further possibilities for scaling down monolithic photonic circuits. By fabricating arrays of microdisks with different diameters and thus different resonant wavelengths, it should be possible to address each microdisk by tuning the excitation wavelength. Furthermore, the WGMs that couple to emission will also differ, which would be useful for implementing on-chip wavelength-division multiplexing. Integration of single photon emitting CNTs with silicon photonics may open up new opportunities for quantum optics on a chip.
